

Q: What should I check when PostgreSQL transactions are timing out?

A: Check for long-running transactions, database locks, slow queries, high CPU or memory utilization, connection saturation, and application timeout settings.

Q: What causes PostgreSQL connection pool exhaustion?

A: Connection pool exhaustion can occur when the application has too many concurrent requests, connections are held for too long, transactions are slow, or the configured pool size is too small.

Q: How can I investigate active PostgreSQL connections?

A: Check the number of active and idle connections, identify applications consuming connections, and compare the number of connections with the PostgreSQL connection limit.

Q: How can long-running transactions affect PaymentService?

A: Long-running transactions can hold database connections and locks for an extended period. This can increase query latency and contribute to connection pool exhaustion or transaction timeouts.

Q: What should I check when an application reports database timeout errors?

A: Check database availability, active connections, transaction duration, query performance, locks, connection pool utilization, and PostgreSQL resource utilization.

Q: How is connection pool exhaustion related to transaction timeouts?

A: If database connections remain occupied by slow or long-running transactions, new requests may wait for an available connection. Eventually the request can exceed its configured timeout.
